## ERROR CONCEALMENT FOR VOICE TRANSMISSION SYSTEM

### BACKGROUND OF THE INVENTION

The invention disclosed and claimed herein generally pertains to communication systems for transmitting voice information through an interface, wherein transmitted data may be represented by successive frames of data samples. More particularly, the invention pertains to wireless communication systems of the above type wherein the data frames are transmitted through a synchronous communication channel, and some of the frames may be erased or lost due to interference. Even more particularly, the invention pertains to a method and apparatus for systems of the above type, wherein lost frames are detected and errors caused by the lost frames are concealed to improve voice quality at the system receiver.

As is well known in the art, there is increasing interest in providing computers, telephones and other small electronic devices with the capability to connect and communicate wirelessly with one another, over short ranges, by means of radio links. Such capability could conceivably eliminate or substantially reduce the need for cables or infrared connections between devices such as computers and peripherals, between phones and headsets, and between televisions and their remote controls. Moreover, a number of devices could thereby be readily

joined together to form small networks, or multiple networks, within a building or even within a single room.

The assignee herein, a major supplier of mobile telecommunications equipment and systems, has initiated a program to develop a wireless communication capability of the above type. This program, known as the "Bluetooth Short Range Radio System," is now supported by a number of large electronics industry vendors and suppliers. A Bluetooth specification has now been developed, for a very small radio module which is to be built into computers, telephones, entertainment equipment, and the like. Bluetooth devices are intended to communicate at 2.45Ghertz over the Industrial, Scientific and Medical (ISM) band, which is unlicensed and globally available. Bluetooth may be adapted for either asynchronous communication, i.e., transmission in only one direction at a time, or for synchronous communication, i.e., transmission in both directions simultaneously.

It has been found that communication over the Bluetooth synchronous communication channel (SCO) for voice transmission can be very sensitive to interference from sources that use the same open ISM band, such as WLAN 802.11b devices, as well as from microwave ovens and the like. The voice coder or codec used for voice coding on the SCO channel, which is a Continuously Variable Slope Delta modulation (CVSD) voice codec, is sufficiently robust for limited bit error conditions resulting from such interference. However, entire frames of data can be erased or lost due to the interference, and for this situation the codec robustness does not help. Moreover, in accordance with the present state of the art for Bluetooth, a lost data frame is muted and replaced with a special bit sequence of 0, 1, 0, 1 . . . in the CVSD bitstream. This practice has been shown to reduce the transient nature of the frame erasure or loss. However, it does not

improve voice quality, particularly during a high percentage of erasures caused by for instance 802.11b WLAN interference.

## SUMMARY OF THE INVENTION

5        Embodiments of the invention are directed to an error concealment scheme for improving voice quality during interference generated frame erasures in a voice transmission system. More particularly, a pitch synchronous waveform based error concealment scheme is disclosed, which would remove the effect of the lost data frames and improve subjective voice quality at the system decoder. Important benefits provided by embodiments of the invention include  
10        simplicity or reduced complexity in construction and operation. Moreover, the invention requires no information from the voice codec generating the pulse code modulated (PCM) waveform, and is thus independent therefrom. In a very useful embodiment lost data frames are muted by the CVSD voice codec, as described above. Embodiments of the invention are very usefully employed in connection with the Bluetooth communication system.

15        The term "data frame" is used herein to refer to a frame of data having a packet length of the systems such as Bluetooth, GSM and UMTS. A "pitch synchronous frame," as used herein, has a pitch synchronous frame period which is the period between the positive peaks of two consecutive waveforms. Usually the pitch period is longer than the packet frame so that a pitch synchronous frame as defined in the PCM error concealment system can contain a lost packet or  
20        data frame as a subset of the total pitch synchronous frame.

In one embodiment of the invention, a method is provided for improving quality of voice information at the receiving side of a voice communication system, wherein the voice information is transmitted through an interface and is represented by a succession of data frames

respectively contained in a succession of pitch synchronous frames, at least one of the data frames subject to being lost as a result of interference in the interface. The method comprises the steps of detecting a particular pitch synchronous frame which has lost a data frame at the receiving side, or system receiver, and replacing the particular pitch synchronous frame with a  
5 replica of a pitch synchronous frame which immediately precedes the particular pitch synchronous frame in the succession of pitch synchronous frames.

In a preferred embodiment, the detecting step is carried out by computing a threshold value associated with the particular pitch synchronous frame, and selectively comparing an average magnitude of the particular frame with the threshold value. Preferably, a difference  
10 value is computed by subtracting the average magnitude of the particular pitch synchronous frame from an average magnitude associated with the immediately preceding pitch synchronous frame. Loss of the particular frame is then indicated if the difference value is found to exceed the threshold value.

An embodiment of the invention may also include the step of estimating a pitch  
15 synchronous period associated with the transmitted voice information. Usually, this is accomplished by generating a train of signal samples from the voice information, wherein the samples collectively represent a succession of signal waveforms. Respective positive peaks of the waveforms are identified, and the period between two consecutive positive peaks based on an adaptive threshold is computed to provide the pitch synchronous frame period estimate.

## 20 BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a block diagram showing a communication system which is provided with an embodiment of the invention.

Figure 2 is a block diagram showing an embodiment of the invention.

Figure 3 is a waveform diagram showing a pitch synchronous frame which has lost a data frame.

Figure 4 shows the waveform diagram of Figure 3 after correction in accordance with an embodiment of the invention.

### DETAILED DESCRIPTION OF A PREFERRED EMBODIMENT

Referring to Figure 1, there is shown a communication system 10 for transmitting an audio frequency signal  $s(n)$  through or across an air interface 12, from the transmitter side 14 of the interface to the receiver side 16 thereof. Communication system 10 comprises a transmitter 18 and components associated therewith, located on transmitter side 14, and further comprises a receiver 20 and components associated therewith, located on receiver side 16. Transmitter 18 and receiver 20 respectively comprise conventional devices, and only some of their components are shown. While communication system 10 usefully comprises the Bluetooth system referred to above, the invention is by no means limited thereto.

Audio signal  $s(n)$  represents a digital sample value. Accordingly, signal  $s(n)$  is generated by a microphone and an analog-to-digital converter, or other source 22 containing voice or speech components. Accordingly, Figure 1 further shows transmitter 18 provided with a CVSD encoder 24, or voice codec. Codec 24 is usefully operable at 64kb/s and implements a voice encoder algorithm to encode the speech components of signal  $s(n)$ . The encoded signal, comprising a CVSD bitstream of successive signal samples  $x'(n)$ , is transmitted across air interface 12 by a transmission circuit 26 of transmitter 18, and is received by reception circuit 28 of receiver 20. The received signal is then decoded, by a CVSD decoder 32. As stated above,

the encoded voice signal, comprising data samples  $x'(n)$ , is transmitted across air interface 12 through a synchronous communication channel (SCO). The voice signal samples  $x'(n)$  represent a succession of waveforms, each having a positive peak. Successive samples  $x'(n)$  are grouped into sets of data frames, respectively contained in a succession of pitch synchronous frames wherein the length of a pitch synchronous frame is equal to the spacing between two consecutive positive peaks.

As likewise stated above, interference in the air interface 12 can cause a data frame of samples  $x'(n)$  to be lost or erased. System 10 is designed to respond to frame erasure by muting the lost data frame in the CVSD bitstream. In accordance with the invention, it has been recognized that this action will cause a sudden fall in signal energy, in the bitstream position associated with the lost data frame and in its corresponding pitch synchronous frame.

Referring further to Figure 1, there is shown receiver 20 provided with CVSD decoder 32 for decoding the received signal  $x'(n)$  to provide a pulse code modulated (PCM) signal  $x(n)$ , likewise comprising successive signal samples. The signal samples  $x(n)$  are applied to a lost frame concealment device 30, constructed to operate in accordance with an embodiment of the invention as hereinafter described.

Referring to Figure 2, there is shown lost frame concealment device 30 comprising, as its principal components, a waveform pitch estimator (WPE) 34, a lost frame detector (LFD) 36, and an error concealment (EC) block 38. Device 30 further includes a halfwave rectifier 40, which receives the signal samples  $x(n)$  and provides rectified signal  $x_h(n)$  therefrom. WPE 34 is provided to estimate the pitch period of signal  $x(n)$ , and receives the halfwave rectified signal  $x_h(n)$  as an input. Using the halfwave rectified signal reduces the number of signal samples

which must be processed by WPE 34, and also helps to avoid ambiguity during calculation of the pitch period.

In its operation WPE 34 bases detection of pitch period on short time waveform pitch computation and long time pitch comparison. WPE 34 performs a low pass filter operation, to  
5 extract the pitch frequency signals from its input signal. WPE 34 also computes an adaptive value  $2/N_p \sum x_h(n)$ , the average amplitude of its input signal  $x_h(n)$ .  $N_p$  is the number of signal samples between two consecutive positive peaks above a threshold of the waveforms represented by the signal  $x(n)$ , and thus indicates the period between the two positive peaks, which is the pitch synchronous frame period. WPE 34 compares respective samples  $x_h(n)$  with the average  
10 amplitude value, and excludes samples which are less than such value. It will be readily apparent that no sample which is less than the average amplitude value can be a positive peak value of the waveforms represented by the samples. The remaining signal samples  $x_h(n)$ , that is, the samples which exceed the average amplitude, are processed by WPE 34 to identify the samples of maximum positive value, thereby indicating the waveform positive peaks. The  
15 spacing or period between consecutive positive peaks is then determined, to provide the desired pitch period. Pitch period is represented herein by the number of signal samples  $N_p$  between the consecutive positive peaks. The number of samples between positive peaks also define the length or duration of successive pitch synchronous frames.

In a useful embodiment WPE 34 is constructed and operated in accordance with  
20 teachings of US Patent No. 5,970,441, issued October 19, 1999 to F. Mekuria, one of the inventors herein, such as the teachings at column 4, lines 18-67 and column 5, lines 1-10 thereof.

Referring further to Figure 2, there is shown lost frame detector 36 receiving the pitch period estimate  $N_p$  from WPE 34. LFD 36 is also coupled to average magnitude calculator 42, to

receive average magnitude values  $M_{av}$  therefrom. More specifically, calculator 42 is disposed to compute  $M_{avi}$ , the average magnitude of pitch synchronous frame  $i$  of the signal data samples  $x(n)$ . Calculator 42 performs this computation by summing the absolute values of such signal samples. Thus,  $M_{avi}$  is computed as  $M_{avi} = 1/N_p \sum x_a(n)$ , where  $x_a(n) = |x(n)|$  is the absolute value of  $x(n)$ . Hence,  $M_{avi}$  is the sum of  $N_p$  samples of the pitch synchronous frame  $i$ .

As stated above, the detection of a lost frame in the signal waveforms is based on the fact that a sudden fall in signal energy is experienced due to muting of the lost data frame by the SCO communication scheme. Accordingly, LFD 36 is constructed to recognize a lost data frame in pitch synchronous frame  $i+1$  by comparing the average magnitudes for the consecutive pitch synchronous frames  $i$  and  $i+1$  and a threshold value  $T_{mav}$ , wherein  $T_{mav}$  and the frame average magnitudes have the following relationship:

$$T_{mav} = \delta \frac{M_{avi} + M_{avi+1}}{2} \quad \text{Eqn. (1)}$$

In Equation (1)  $M_{avi}$  and  $M_{avi+1}$  are the average magnitudes of pitch synchronous frames  $i$  and  $i+1$ , respectively. The factor  $\delta$  is used to control the level of the threshold and avoid low energy non-vocalic segments of speech signals. Usefully,  $\delta$  varies between 0.8 and 1.2, depending on the amplitude of the incoming signal.

In order to detect a lost data frame, LFD 36 determines whether or not the difference value  $(M_{avi} - M_{avi+1})$  is greater than  $T_{mav}$ . More specifically, a difference value which is greater than  $T_{mav}$  indicates that a data frame in the pitch synchronous frame  $i+1$  has been erased. When this occurs, LFD 36 provides notice to EC block 38. In accordance with the invention, it has been found that computing average magnitude  $M_{av}$  from the absolute values of the  $x(n)$  signal

samples, as described above, significantly enhances the energy difference between a pitch synchronous frame containing a data frame erasure and one with no data frame erasure.

When block 38 is notified that frame  $i+1$  has had a data frame erased, that is, that the difference between the average magnitude of pitch synchronous frame  $i$  and the next frame  $i+1$  is greater than the threshold value  $T_{mavi}$ , then EC block 38 operates to replace pitch synchronous frame  $i+1$  with a pitch synchronous replica of the frame from the immediately preceding pitch period, that is, pitch synchronous frame  $i$ . This rule is alternatively stated as follows:

$$\text{If } (M_{avi} - M_{avi+1}) > T_{mav} : \text{Frame}[X_{i+1}(n) = [X_i(n)] \quad \text{Eqn. (2)}$$

In order to reduce the end effects during PCM waveform replacement, it has been found that a low order low-pass filter (LPF) 44 can be applied to the processed signal. This provides an output signal  $y(n)$ , of significantly improved voice quality.

Usefully, as further shown by Figure 2, a zero crossing detector (ZCD) 46 can be employed to improve the performance of the device 30 during consonant sound segments. Zero crossing detector 46 counts the number of zero crossings per frame of the incoming signal. Consonant sounds are more like noise and thus provide a high ZCD value. When data frame erasure occurs the ZCD value changes dramatically, and can thus be used as an indicator of data frame erasure in the case of consonant sounds.

Referring to Figure 3, there is shown a set of voice waveforms represented by the signal samples  $x(n)$ . Thus, Figure 3 shows waveform 48 for pitch synchronous frame  $i$ . However, a data frame in pitch synchronous frame  $i+1$  has been erased or muted, by interference or the like, as shown by waveform 50. When LFD 36 recognizes this condition, as described above, error concealment block 38 operates to replace the pitch synchronous frame  $i+1$  with a replica of frame  $i$ . This is shown in Figure 4, which depicts output signal  $y(n)$ . The vertical axes in Figures

3 and 4 represent waveform magnitude, and the respective horizontal axes represent sample number.

Many other modifications and variations of the present invention are possible in light of the above teachings. It is therefore to be understood that within the scope of the disclosed

5 concept, the invention may be practiced otherwise than as has been specifically described.
